Parallel mechanism

ABSTRACT

This paper introduces a new metamorphic parallel mechanism based on a reconfigurable revolute (rR) joint and the mechanism consists of three rRPS (rR joint-prismatic joint-spherical joint) limbs. Reconfiguration principle of the rR joint and the rRPS limb is explained, based on which the 3rRPS metamorphic parallel mechanism can be reconfigurable between two working motion types, pure rotation (3R) motion and one translation and two rotation (1T2R) motion. Using the limb geometric constraint model, analytical forward kinematics is solved in a unified way for both motion types. Reciprocal screw based Jacobian is obtained for singularity analysis which is then used for singularity-free workspace analysis. Based on those, maximum singularity-free workspace and kinematics performance based criteria are applied in optimizing basic mechanism parameters considering input and passive joint limitations. A unified objective function with variable design priorities represented by function weights of the two topologies is proposed and examples are illustrated. The introduced new parallel mechanism covers the two very useful motion types, 3R and 1T2R, while the model in the paper provides basis of modeling and optimal design for further applications.

1. Introduction

Parallel mechanisms have been successfully applied as tire test machine [1], industry assembly tools [2], manufacturing center [3], force transducer [4], rehabilitation platform [5] and robotics surgery instrument [6] due to their high load-carrying capacity, good positioning accuracy and low inertia [7] stemmed from their multi-loop geometric structures [8]. Due to fast task change with variable mobility requirements, like rapid customization and diverse environment changing [9], rehabilitation and surgery of different human joints, parallel mechanisms which are reconfigurable have attracted much interest from mechanism researchers. Based on this, metamorphic parallel mechanisms (MPMs) [10], which are a class of mechanisms that possess adaptability and reconfigurability to change permanent finite mobility based on topological structure change, were introduced. Metamorphic parallel mechanisms have all the advantages of traditional parallel mechanisms [11] but with ability of reconfiguring for mobility change.

In this paper, a new metamorphic parallel mechanism with a reconfigurable revolute joint is proposed. The new mechanism has the ability of mobility change between 3R motion and 1T2R motion which are the two very useful motions in parallel mechanism applications and the two widely studied motion types in parallel mechanism research. Novel applications of parallel mechanisms with 3R motion include camera orienting devices [12], robotic joints [13,14], robotic surgery platform [15], and human joint rehabilitation [16]. Parallel mechanisms with 1T2R motion have been applied as flight simulator [17], micro-medical device [18], coordinating–
measuring machine [19] and machining tools [2,20]. However, those two types of parallel mechanisms were treated independently with case-by-case applications. The new metamorphic parallel mechanism proposed in this paper can provide both motion types with the same mechanical structure. This keeps kinematics and dynamics simplicity of lower-DOF parallel mechanisms but provides capability to multi-tasks, like machining different types of components, and rehabilitation of different human joints. The study of this paper will illustrate the reconfiguration concept, unified kinematics analysis and optimal design of the new parallel mechanism, which can be used for the mechanism design and applications. More than that, the proposed reconfiguration method can also be extended to generate more reconfigurable parallel mechanisms.

Current mechanism research shows some basic ways to design reconfigurable mechanisms. One is to change the number of links by link coincidence and self-locking as in [21–24]. It was used in proposing metamorphic mechanisms in the study of decorative cartoon multifingered hand with an articulated palm by link coincidence of a spherical five bar linkage was presented [22]. A general approach for self-locking analysis was done in [23] while various joint types were explained and used in kinematic representations of metamorphic pop-up paper mechanisms in [24].

Another way of reconfiguration is through singularities. One of the cases is to have bifurcated configurations through constraint singularities [25]. Kinematotropic mechanisms were the earliest mechanisms that the permanent mobility could be changed after it passed through the singular positions [26]. Following the study of single-loop and multi-loop kinematotropic mechanisms, parallel mechanisms with bifurcated motion were also constructed [27]. Using the same principle, a parallel mechanism with changed motion for machine tool applications was proposed [28] while a family of parallel mechanisms that have multiple operation modes were presented [29,30]. Using linear transformations, new 1R2T parallel mechanisms with a bifurcated rotation motion on two orthogonal directions [31] were synthesized. In addition to constraint singularities, through both Type 1 [32] and Type 2 [33] singularities, parallel mechanisms can be also reconfigured between different motion types.

Other methods of reconfiguring mechanisms include special trajectory planning [34], variable actuation modes [35,36] and variable geometric joints [10,37]. The last method is to apply geometric constraint to joints to change the joint property and has been recently developed a lot. Variable topologies of kinematic joints and their topological representation were presented in [37]. Based on a reconfigurable Hooke (rT) joint, various metamorphic parallel mechanisms [10,38] have been synthesized and a general construction method using screw theory was introduced [39]. Similarly a metamorphic parallel mechanism with the ability of performing phase change and orientation switch was proposed by introducing a metamorphic kinematic pair [40] and a class of metamorphic parallel mechanisms was designed using a variable-axis (vA) joint [41]. Recently, unified kinematics modeling and singularity analysis of metamorphic parallel mechanisms have been investigated in [42,43]. By designing a reconfigurable universal joint, a 3-CUP parallel mechanism was proposed to reconfigure into two motion types [44].

Using similar principle to the rT joint [10] and vA joint [41], this paper introduced a reconfigurable revolute (rR) joint of which the rotation axis can be altered freely on a plane. Based on this, three rRPS limbs are used to construct a metamorphic parallel mechanism which can change its platform mobility between 3-DOF spherical motion and 3-DOF 1T2R motion. This paper then shows a unified kinematics model for analytic solutions of the forward and inverse displacement analysis covering the two different motion types. Reciprocal screw based Jacobian matrix is also used to represent the singularity loci. Following this, a method of obtaining optimized structure parameters to have the maximum singularity-free workspace and good kinematics performance for both motion types is proposed.

In the following, the paper is arranged as: Section 2 introduces the reconfigurable revolute joint and the rRPS limb with its geometric constraint analysis in screw theory; following this, mobility change of the 3rRPS metamorphic parallel mechanism is demonstrated in Section 3 and unified kinematics analysis is solved in Section 4; over all Jacobian matrix in terms of reciprocal screws is derived to obtain singularity loci and singularity-free workspace is then illustrated in Section 5; based on these, parameter effect on maximum
singularity-free workspace is carried out in Section 6 and optimal design is then demonstrated in Section 7; reconfiguration strategy and the rT joint design are discussed in Section 8; conclusions make up Section 9.

2. The reconfigurable revolute (rR) joint and the rRPS limb

As in Fig. 1(a), the reconfigurable revolute joint, named rR joint, consists of a ring base, a rotation bar and a joint link. The joint link which is normally connected to a mechanism limb and perpendicular to the rotation bar rotates about the rotation bar with axis \( u \). The reconfiguration comes from that the rotation bar can be rotated along the groove of the ring base about the direction \( n \) which is the normal vector of the ring base plane \( \Sigma \). This allows the revolute joint axis \( u \) to be alterable about \( n \) on the plane \( \Sigma \) and fixed along the groove. This changes the contribution of the rR joint in a parallel mechanism assembly and will make the mechanism reconfigurable.

The RPS limb consisting of an rR joint, a prismatic joint and a spherical joint, is shown in Fig. 1(b). The function of an rRPS limb in a parallel mechanism is equivalent to a general RPS limb but with an additional reconfigurable rotation axis of the revolute joint.

Set a limb coordinate system \( ^1o_x^1y^1z \) at the intersecting point of the rotation bar and the joint link on the plane \( \Sigma \), where \(^1x\) axis and \(^1y\) axis are on the plane \( \Sigma \) while \(^1z\) axis is along \( n \). The twist system of the rRPS limb is given as:

\[
\begin{align*}
\{S_1\} &= \begin{bmatrix}
S_{11} = [u^T, 0 \times u^T] \\
S_{12} = [0, s^T] \\
S_{13} = [u^T, a^T \times u^T] \\
S_{14} = [s^T, a^T \times s^T] \\
S_{15} = [u^T \times s^T, a^T \times (u^T \times s^T)]
\end{bmatrix}
\end{align*}
\]  

(1)

where \((\cdot)^T\) is the transpose of vector/matrix \((\cdot)\), \( u = (\cos \theta, \sin \theta, 0)^T \), \( s = (-\cos \sin \theta, \cos \cos \theta, \sin \alpha)^T \) is the unit vector along the limb, \( 0 \) is a \( 1 \times 3 \) zero vector and \( a \) is the position vector of the spherical center. In Eq. (1), the first twist is for the rR joint, the second is generated from the prismatic joint, and the last three are generated from the spherical joint. \( \theta \) is the angle between the rotation bar \( (u) \) and the \(^1x\) axis, \( \alpha \) is the angle between the limb \( (s) \) and its projection on plane \(^1x\) \((plane \Sigma)\). In the twist notation \( ^1S_{ij} \), the first subscript \( i \) denotes the limb number, the second subscript \( j \) denotes the joint number within the limb and the leading superscript indicates the local frame.

The five twists in Eq. (1) form a five-system [45]. Thus, there is one reciprocal screw to Eq. (1) in the limb constraint system as

\[
\{S_1\}^{-1} = \{u, a \times u\}.
\]

(2)

This gives a constraint force acting along a line passing through the spherical joint center with a direction parallel to the rotation axis \( (u) \) of the rR joint. By altering the revolute joint axis \( u = (\cos \theta, \sin \theta, 0)^T \) with variable \( \theta \) the constraint force in Eq. (2) is alterable and will change the constraint to the platform as analyzed in the following 3rRPS metamorphic parallel mechanism.

3. The 3rRPS metamorphic parallel mechanism and its reconfiguration

The 3rRPS metamorphic parallel mechanism as in Fig. 2 has three rRPS limbs symmetrically located on the base circle with radius \( r_b \) through the rR joints and on the platform circle with radius \( r_a \) through spherical joints. Let points \( A_i \) and \( B_i \) denote the spherical joint center and the rR joint center in limb \( i (i = 1, 2, 3) \) respectively. \( u_i \) is the rotation axis of the rR joint in limb \( i \). Locate a global coordinate system \( oxyz \) at the geometric center \( o \) of the base with the negative part of \( y \) axis passing through rR joint center \( B_1 \) and z axis perpendicular to the base plane formed by \( B_1B_2B_3 \). Then, \( x \) axis is parallel to \( B_2B_3 \) as in Fig. 2. Based on symmetry, all the ring base plane \( \Sigma \), of the rR joint in limb \( i \) intersects the z axis with angle \( \phi \) which is named rR joint base location angle. Let \( a_i \) and \( b_i \) denote the vectors of points \( A_i \) and \( B_i \) in the coordinate system \( oxyz \), \( l_i \) be the limb length between the spherical joint center \( A_i \) and the rT joint center \( B_i \). Similarly, a moving coordinate system \( o.x'y'z' \) is attached at the platform center \( o' \) with the negative part of \( y' \) axis passing through spherical joint center \( A_i \) and \( z' \) axis perpendicular to the platform plane formed by \( A_1A_2A_3 \).

Based on the above description, the geometric constraint of the 3rRPS is described in two parts. The first part expresses the length of the limbs

\[
(Ra'_i + p - b_i)^2 = l_i^2 \quad (i = 1, 2, 3)
\]

(3)

and the second part describes the constraint that each limb is perpendicular to the rotation axis \( u_i \) of the rR joint:

\[
(Ra'_i + p - b_i)^T \cdot u_i = 0 \quad (i = 1, 2, 3)
\]

(4)

where \( R \) is the rotational matrix from the moving coordinate system to the global coordinate system \( oxyz \), \( p = (p_x, p_y, p_z)^T \) is the vector of the moving coordinate center \( o' \) expressed in the global coordinate system. \( a_i' \) is the position vector of spherical joint center \( A_i \) expressed in the moving coordinate system \( o.x'y'z' \).
Based on the six constraint equations in Eqs. (3) and (4), the three independent rotation parameters in \( R \) and the three translation parameters in \( p = (p_x, p_y, p_z) \) can be fully determined when \( i \) is given as actuation input of each prismatic joint. Thus, equations in Eq. (3) are related to the actuation and equations in Eq. (4) determine the mobility of the 3rR MPM. Based on the reconfiguration of the rR joint with variable \( u_i \) by rotating the ring base, the 3rR MPM is reconfigurable and can have the following different topologies with two different motion types.

**Case 1.** The three rR joint axis \( u_i \) are independent.

This is the general case as in Fig. 2, the position vector \( p = (p_x, p_y, p_z) \) can be solved from the three equations in Eq. (4) as

\[
p^T = \begin{bmatrix} (b_1 - Ra_i)^T u_1 \\ (b_2 - Ra_i)^T u_2 \\ (b_3 - Ra_i)^T u_3 \end{bmatrix} \cdot \begin{bmatrix} u_1 & u_2 & u_3 \end{bmatrix}^{-1}.
\]  

(5)

Thus, the translation parameters can be linearly solved for a given rotation matrix \( R \) but not inversely. Thus, considering kinematics simplicity, this topology is taken as pure rotation (3R) motion with parasitic translation motion that can be obtained from Eq. (5).

Before going to **Case 2**, the following Cayley formula [46] is introduced and will be used to describe the rotation between the moving coordinate system and the global coordinate system as matrix \( R \):

\[
R = \Delta^{-1} \begin{bmatrix} 1 + c_1^2 - c_2^2 - c_3^2 & 2(c_1c_2 - c_3) & 2(c_1c_2 + c_3) \\ 2(c_1c_2 - c_3) & 1 - c_1^2 + c_2^2 - c_3^2 & 2(c_2c_3 - c_1) \\ 2(c_1c_2 + c_3) & 2(c_2c_3 + c_1) & 1 - c_1^2 - c_2^2 + c_3^2 \end{bmatrix}
\]  

(6)

where \( \Delta = 1 + c_1^2 + c_2^2 + c_3^2, c_1, c_2 \) and \( c_3 \) are the Rodriguez–Hamilton parameters and \( c_1 = k_x \tan(\gamma/2), c_2 = k_y \tan(\gamma/2), c_3 = k_z \tan(\gamma/2) \), which describes a 3D rotation about an axis \( k(k_x, k_y, k_z) \) with angle \( \gamma \).

Cayley formula uses the three independent Rodriguez–Hamilton parameters to represent 3D rotation motion and shows a big advantage in simplifying the following geometric constraint equations for mobility analysis and also on singularity and workspace representation in Section 5.

**Case 2.** The three rR joint axis \( u_i \) are dependent

Based on the symmetrical property, there are two dependent cases.

1. **Two \( u_i \) are dependent**

This is the case when two \( u_i \) are parallel to each other and there are three cases \( (u_1 = u_2, u_1 = u_3, \) or \( u_2 = u_3) \). An example of \( u_1 = u_2 \) is in Fig. 3(a) and due to the symmetry \( u_1, u_3 \) should be parallel to the common line of the two base ring planes of the rR joints in limb 1 and limb 3. Then from Eq. (4) there is:

\[
\begin{align*}
p^T u_1 &= (b_1 - Ra_i)^T u_1 \\
p^T u_2 &= (b_2 - Ra_i)^T u_2 \\
0 &= (b_1 - b_2 - Ra_i + Ra_i)^T u_1
\end{align*}
\]  

(7)
From Eq. (7) two of the three translation parameters \((p_x, p_y, p_z)\) in \(p\) can be linearly solved from the first two equations while the third equation only relates to the rotation parameters in \(R\). By substituting Cayley formula from Eq. (6) into the third equation in Eq. (7), there is

\[
c_3 = f\left(1, c_1, c_2, c_1^2, c_2^2\right)
\]

where \(f(\cdot)\) is a function of unknown power products in the bracket, with real constant coefficients depending on the input and mechanism dimensional parameters only. This further shows that the rotation about \(z\) axis can be linearly solved by the rotations about the other two axes. For simplicity, the mechanism is considered to have two main rotations about \(x\) axis and \(y\) axis. Thus, the mechanism has one translation and two rotation (1T2R) motion in this case.

(2) Three \(u_i\) are dependent

This is the case only when all the three \(u_i\) are on the base plane as in Fig. 3(b) where \(u_1 = (1, 0, 0)^T, u_2 = (-1/2, \sqrt{3}/2, 0)^T, u_3 = (-1/2, -\sqrt{3}/2, 0)^T\), then \(u_1 + u_2 + u_3 = 0\), and there is

\[
\begin{align*}
   p_x &= (b_1 - Ra_1^1)^T u_1 \\
   p_y &= (b_2 - Ra_2^2)^T u_2 \\
   c_3 &= 0
\end{align*}
\]

Similar with Eq. (7), two of the three translation parameters \((p_x, p_y, p_z)\) in \(p\) can be linearly solved from the first two equations while the third equation provides a constraint among the rotation parameters in \(R\). This can be further detailed as:

\[
\begin{align*}
   p_x &= (b_1 - Ra_1^1)^T u_1 \\
   p_y &= (b_1 - Ra_1^1)^T u_1 + 2(b_2 - Ra_2^2)^T u_2 / \sqrt{3} \\
   c_3 &= 0
\end{align*}
\]

Thus translations along \(x\) axis and \(y\) axis can be linearly solved from the rotation motion while there is no rotation about \(z\) axis. The parallel mechanism in this case is considered to have one translation along the \(z\) axis and two rotations about \(x\) axis and \(y\) axis.

To summarize the above analysis, the 3rRPS MPM can have either pure rotation (3R) motion with parasitic translations or one translation and two rotation (1T2R) motion by reconfiguring the rotation axis of the \(rR\) joint into different directions. It should be noticed that there are infinite numbers of configurations with pure rotation motion by altering the \(rR\) joint in each limb as far as the three rotation axis vectors are not dependent. There are only four cases with 1T2R motion as stated in Case 2.

4. Unified kinematics modeling and analytical displacement analysis

The inverse displacement analysis of the 3rRPS metamorphic parallel mechanism is to obtain the actuation parameters (limb length \(l\)) based on the given platform position and orientation. When giving the platform position \(p\) \((p_x, p_y, p_z)\) and orientation \(R\)
described in the global coordinate system in Fig. 1, the actuation inputs which are the limb lengths can be calculated directly from Eq. (3):

$$l_i = \sqrt{(R \mathbf{a}_i + p - b_i)^2} \quad (i = 1, 2, 3). \tag{11}$$

This is the same for all the topologies with different mobility but it should be mentioned that, the platform position and orientation parameters cannot be given freely. They should follow the geometric constraint relations analyzed in Section 3 that the translations are calculated by given orientation for 3R motion case and two rotations and one translation can be given arbitrarily for the 1T2R motion case.

On contrary to the inverse one, forward displacement analysis is to solve the platform position $\mathbf{p}$ ($p_x, p_y, p_z$) and orientation $\mathbf{R}$ when giving the corresponding actuation parameters ($l_i$) for each topology. The strategy for the 3rRPS metamorphic parallel mechanism is to use the limb parameters to express the spherical joint center vector $\mathbf{a}_i$ to form the constraint equations based on the platform geometry. To do this, a limb coordinate system $\Sigma_{l_i}$ is attached to each rR joint as in Fig. 4, where $z$ axis is along the normal $\mathbf{n}$ of the base plane of the rR joint and $y$ axis intersects the $z$ axis. The following solving procedure gives a unified forward kinematics analysis valid for all topologies of the 3rRPS MPM with different mobility.

Based on the above analysis and the coordinate systems of the 3rRPS MPM in Fig. 4, geometric constraints of the mechanism can be given as:

$$\begin{align*}
\mathbf{a}_1 &= \mathbf{b}_1 + R_x(0)R_y(\phi - \pi/2)R_z(\theta_1)l_1(0, \cos \alpha_1, \sin \alpha_1) \\
\mathbf{a}_2 &= \mathbf{b}_2 + R_x(2\pi/3)R_y(\phi - \pi/2)R_z(\theta_2)l_2(0, \cos \alpha_2, \sin \alpha_2) \\
\mathbf{a}_3 &= \mathbf{b}_3 + R_x(4\pi/3)R_y(\phi - \pi/2)R_z(\theta_3)l_3(0, \cos \alpha_3, \sin \alpha_3)
\end{align*} \tag{12}$$

where $l_i$ is the length of limb $i$, $R_k(g)$ represents a rotation about axis $k$ with angle $g$ and is used to translate the vector of the spherical joint center in the limb coordinate system to the global coordinate system in Fig. 4. $\theta_i$ describes the direction of the rR joint rotation axis $u_i$ and $\alpha_i$ is the angle between the limb and its projection on the $x'y'z'$ plane (plane $\Sigma$) in limb $i$.

Based on this, the triangle of the platform geometry can be described as:

$$\begin{align*}
(\sqrt{3}R_1)^2 &= (\mathbf{a}_1 - \mathbf{a}_2)^2 \\
(\sqrt{3}R_2)^2 &= (\mathbf{a}_1 - \mathbf{a}_3)^2 \\
(\sqrt{3}R_3)^2 &= (\mathbf{a}_2 - \mathbf{a}_3)^2
\end{align*} \tag{13}$$

Substituting Eq. (12) into Eq. (13) and applying $\cos \alpha_i = (1 - t_i^2)/(1 + t_i^2)$, $\sin \alpha_i = 2t_i/(1 + t_i^2)$, there is

$$\begin{align*}
f_1(1, t_1^2, t_2^2, t_3^2, t_1^2 t_2^2, t_1^2 t_3^2, t_2^2 t_3^2) &= 0 \\
f_2(1, t_1^2, t_2^2, t_1^2 t_2^2, t_1^2 t_3^2, t_2^2 t_3^2) &= 0 \\
f_3(1, t_2^2, t_3^2, t_2^2 t_3^2, t_3^2 t_1^2, t_3^2 t_2^2) &= 0
\end{align*} \tag{14}$$

![Fig. 4. Unified kinematics modeling of the 3rRPS with perpendicular constraint screws.](image-url)
where \( f_i(\bullet) \) is a linear function of the power products in the bracket with coefficients depending on known parameters only, \( t_i \) represents \( \tan(\alpha_i/2) \).

By using Sylvester’s dialytic elimination method \([32]\) for the first two equations in Eq. (14), there is

\[
f_4\left( t_1, t_3, t_2^2, t_2^3, t_3^2, t_3^3, t_1^2, t_2^4, t_2^5, t_3^4, t_3^5, t_1^3, t_2^6, t_2^7, t_3^6, t_3^7 \right) = 0
\]  

(15)

where \( f_4(\bullet) \) is a linear function of the power product in the bracket with coefficients depending on known parameters only. Then, following the same method for Eq. (15) and the third equation in Eq. (14), a polynomial with only unknown \( t_3 \) can be obtained as:

\[
\sum_{i=0}^{16} h_i t_3^i = 0
\]  

(16)

where coefficient \( h_i \) are the real constants depending on input data only.

This shows that a univariate equation in \( t_3 \) of degree 16 is obtained.

Solving Eq. (16), sixteen solutions of \( t_3 \) can be obtained. Then, \( t_3 \) can be solved by substituting each solution of \( t_3 \) into the third equation in Eq. (14) and selecting the roots satisfying Eq. (15). Following this, \( t_1 \) can be solved by substituting each pair of solutions of \( t_2 \) and \( t_3 \) into the first equation in Eq. (14) with proof of the second equation in Eq. (14). Based on this, sixteen pair of solutions of \( t_1 \), \( t_2 \), \( t_3 \) are obtained and the spherical joint center \( A_i \) can be calculated by substituting \( \alpha_i = 2\arctan(t_i) \) into Eq. (12). Then, the platform position and orientation can be determined using the three spherical joint centers with Fig. 4 as:

\[
\begin{align*}
\mathbf{z}' &= (a_2 - a_1) \times (a_3 - a_1) / \| (a_2 - a_1) \times (a_3 - a_1) \| \\
\mathbf{x}' &= (a_2 - a_3) / \sqrt{3r_a} \\
\mathbf{y}' &= \mathbf{z}' \times \mathbf{x}' \\
\mathbf{r} &= (\mathbf{x}', \mathbf{y}', \mathbf{z}') \\
\mathbf{p} &= a_1 + r_a \mathbf{y}' 
\end{align*}
\]

(17)

This shows the unified forward kinematics solution of the 3rRPS metamorphic parallel mechanism for both the 3R motion and the 1T2R motion.

5. Singularity loci and singularity-free workspace

5.1. Singularity loci based on Jacobian matrix with reciprocal screws

The infinitesimal twist \([47]\) of the moving platform of the 3rRPS MPM can be written as the linear combination of instantaneous twists of each limb:

\[
\mathbf{S}_C = \phi_1 \mathbf{S}_{11} + \dot{\mathbf{I}}_1 \mathbf{S}_{12} + \phi_2 \mathbf{S}_{13} + \phi_3 \mathbf{S}_{14} + \phi_5 \mathbf{S}_{15} \quad (i = 1,2,3)
\]

(18)

where \( \mathbf{S}_C \) represents the infinitesimal twist of the moving platform, \( \mathbf{S}_{ij} \) \((i = 1,2,3,4,5) \) denotes the unit screw of the \( jth \) 1-DOF joint in limb \( i \), \( \dot{\mathbf{I}}_i \) is the distance rate of the prismatic joint in limb \( i \), \( \phi_i \) \((j = 1,3,4,5) \) represents the angular rate of the rR joint and spherical joint in limb \( i \).

By locking the active joints in the limbs temporarily and taking reciprocal product on both sides of \( (18) \), there is

\[
\begin{bmatrix} \mathbf{S}_{1} \mathbf{S}_{2} \mathbf{S}_{3} \end{bmatrix}^T \mathbf{S}_C = \begin{bmatrix} 0 & I \end{bmatrix}^T (i = 1,2,3)
\]

(19)

where \( \mathbf{S}_{1} \) is the reciprocal screw of geometric constraint to all motion screws in limb \( i \) and it passes through the spherical joint center with direction parallel to rotation axis \( \mathbf{u}_i \) of the rR joint as in Eq. (2). \( \mathbf{S}_{2} \) is the actuation screw reciprocal to all motion screws in Eq. (18) except the prismatic joint screw \( \mathbf{S}_{3} \) and it is collinear with the limb.

Equations in \( (19) \) for the three limbs can be rewritten in matrix form as:

\[
\begin{bmatrix} \mathbf{S}_{11} \mathbf{S}_{12} \mathbf{S}_{13} \\
\mathbf{S}_{21} \mathbf{S}_{22} \mathbf{S}_{23} \\
\mathbf{S}_{31} \mathbf{S}_{32} \mathbf{S}_{33} \end{bmatrix} \mathbf{S}_C = \mathbf{J} \mathbf{S}_C = \begin{bmatrix} \mathbf{a}_1 \times \mathbf{u}_1 & \mathbf{u}_1 \\
\mathbf{a}_2 \times \mathbf{u}_2 & \mathbf{u}_2 \\
\mathbf{a}_3 \times \mathbf{u}_3 & \mathbf{u}_3 \\
\mathbf{b}_1 \times s_1 & s_1 \\
\mathbf{b}_2 \times s_2 & s_2 \\
\mathbf{b}_3 \times s_3 & s_3 \end{bmatrix} \begin{bmatrix} 0 \\
0 \\
0 \\
\dot{\mathbf{l}}_1 \\
\dot{\mathbf{l}}_2 \\
\dot{\mathbf{l}}_3 \end{bmatrix}.
\]

(20)

In Eq. (20), \( \mathbf{J} \) is the 6 by 6 Jacobian matrix which maps velocities between the manipulator and the actuation input. Once the manipulator meets singular configurations, this mapping loses its function and the rank of the Jacobian matrix decreases to be less than 6.
This can be also interpreted that the six constraint forces in $J$ are linearly dependent. Inversely, identifying the dependent conditions for the constraint forces in the workspace will reveal the singular configurations of the manipulator. In order to demonstrate this, some dimensionless parameters with physical constraints are given as: the platform radius $r_p = 1$, base radius $r_b = 2$, $\phi = \pi/2 - \operatorname{ArcSin}(\sqrt{3}/3)$ representing that the three normal vectors of the three rR joints are perpendicular to each other.

Type 2 singularities appear when the determinant of $J$ equals to zero. Based on the rotation matrix $R$ in (6) and mobility analysis in Section 3, the determinant of $J$ is given by:

$$
J = \begin{cases} 
\begin{array}{l} 
\sum_{i=1}^{3} f_5(c_i, c_2, c_3, ...) \\
\sum_{i=1}^{3} f_6(c_i, c_2, c_3, ...
\end{array} 
\end{cases} 
\begin{array}{l}
3R \text{ motion} \\
1T2R \text{ motion}
\end{array}
$$

(21)

where $f_5$ is a function of $c_1$, $c_2$ and $c_3$ with their products up to 10th order for the topologies with 3R motion and $f_6$ is a function of $c_1$, $c_2$ and $p_z$ with their products up to 11th order for the topologies with 1T2R motion. Those parameters are used respectively to represent the singularity points of the platform. By equalling Eq. (21) to zero, all singular points can be found and some examples are illustrated in Figs. 5 and 6.

In Fig. 5, the singularity loci of the 3rRPS MPM with 1T2R motion ($\theta_1 = \theta_2 = \theta_3 = 0$) is shown. It can be seen that the loci is symmetrical due to the symmetrical limb arrangement. Two singular configurations and their corresponding points on the singularity loci are shown in Fig. 5. It agrees with the conclusion [48] that in singularity configurations the four planes, the platform plane and a plane from each limb formed by the actuation force and constraint force in the limb, intersect at one point which makes the rank of the Jacobian matrix $J$ zero. It can be also found that when $p_z$ is close to zero which is that the platform is close to the base, there are more possibilities to meet singularity configurations. However, in real applications, the platform will work with positive $p_z$ much bigger than zero for which the singularity loci is quite uniform and represented by the tetrahedron shaped surface with an open side along the $z$ direction and a vertex at the zero point with $c_1 = c_2 = p_z = 0$ as in Fig. 5.

As analyzed in Section 3, there are various topologies of the 3rRPS MPM with 3R motion by changing the rR joint rotation axes to different directions. The following shows singularity loci of four cases in Fig. 6. It can be seen that when $\theta_1 = \theta_2 = \theta_3$, the singularity loci are symmetrical due to the symmetrical limb arrangement. The case with $\theta_1 = \theta_2 = \theta_3 = \pi/2$ gives similar spherical parallel mechanism to the pyramid parallel mechanism [49]. When the three rR joint axes do not have the same angle $\theta$, the loci is not symmetrical as shown in Fig. 6(b). Generally, the space close to the center ($c_1 = c_2 = c_3 = 0$) is separated into upper and lower part by the loci which are the main singularities in the mechanism workspace as shown in the following section.

5.2. Singularity-free workspace

In the 3rRPS MPM, each limb length has two limits (lower and upper) which constrain the actuation range and determine the workspace of the platform. Thus, the platform workspace boundaries can be expressed by the two limits $l_{\text{max}}/\text{min}$, following the geometric constraints in Eqs. (3) and (4):

$$
(R \mathbf{a}_i^l + \mathbf{p} - \mathbf{b})^2 = l_i^{2 \text{max}/\text{min}} \quad (i = 1, 2, 3).
$$

(22)

Similar to the singularity representation, the independent parameters are used to illustrate the boundary with $(c_1, c_2, c_3)$ for the 3R motion and $(c_1, c_2, p_z)$ for the 1T2R motion. Two examples are shown in Fig. 7(a) and (b) in which the following parameters are used: spherical joint rotation angle $\leq \pi/3$ rad, rR joint rotation angle $\leq \pi/3$ rad, limb length $1.6 \leq l \leq 2.88$.

Fig. 7(a) shows that workspace of the 1T2R case only exists in the area with $p_z$ between 1 and 3 based on the geometric parameters and constraints given. Most of the part is singularity-free as seen in the combination figure with the singularity loci in Fig. 7(a). Differently, workspace of the 3R case has symmetrical parts with respect to the plane $c_3 = 0$ as in Fig. 7(b) and they are corresponding to positive and negative rotations about $z$ axis. Comparing with the singularity loci, the workspace is separated into two singularity-

\[(c_1=0.5, c_2=-0.5, p_z=0.3) \quad (c_1=0.2, c_2=-0.79, p_z=3)\]

Fig. 5. Singularity loci and two singular configurations of the 1T2R case ($\theta_1 = \theta_2 = \theta_3 = 0$).
free parts. To avoid singularities, the mechanism needs to work with positive or negative z-axis rotation only. The way to define singularity-free workspace in this section will be used as in the optimal design in the following section.

6. Parameter effect on maximum singularity-free workspace

Singularity-free workspace can be taken as the primary performance index for a parallel mechanism and is an important topic in mechanism design. This section aims at exploring effect of some key parameters of the 3rRPS MPM on its singularity-free workspace. Each topology of the 3rRPS MPM is a parallel mechanism and to show the effect by covering all working topologies with different motion types is a challenge. In the following, the two main topologies with 1T2R motion (θ₁ = θ₂ = θ₃ = 0) and 3R motion (θ₁ = θ₂ = θ₃ = π/2) will be considered together.

Based on the kinematics model shown in Fig. 4, key parameters of the 3rRPS MPM are the base and platform sizes (r_b and r_a), rR joint base location angle ϕ and the limb length range (l_min ≤ l ≤ l_max) which is the same for all three limbs. Mechanical constraints including maximum passive joint angles and limb interference should also be considered in the calculation. In the following, passive joint angles are limited in the range as -ψ_max ≤ ψ_i ≤ ψ_max, where ψ_i denotes rotation angle from its home position of any revolute joint, and spherical joint along three orthogonal directions one of which is along the limb at the home position. ψ_max is given π/3 in this paper. The minimum distance between any two limbs is limited to be 0.01 to avoid limb interference.

In the following, effect of the key parameters (r_a, r_b, ϕ, l) on maximum singularity-free workspace V will be illustrated for the two topologies with 1T2R motion (θ₁ = θ₂ = θ₃ = 0) and 3R motion (θ₁ = θ₂ = θ₃ = π/2). V is calculated as the volume inside of the workspace boundaries and the singularity surface as demonstrated in Section 5.2.

(1) Effect of limb length range (l_min ≤ l ≤ l_max).

Based on the kinematics, it can be imagined that limb length range limits the translation along z axis of the 1T2R motion and both of them can be as large as infinite. But this is different for the 3R motion with parasitic translation motion with which the limb length has minimum and maximum values even if there is no other constraint. This is the reason that limb length range is selected as one of the parameters for optimization as an arbitrarily selected limb length range may not cover the effective workspace of the 3R motion. By using dimensionless values r_a = 1, r_b = 2, l_max = 1.8l_min, workspace volume V with respect to different l_min (from 1.3 to 4) under different rR joint base location angle ϕ for the two topologies are shown in Fig. 8. In Fig. 8(a), it can be seen that the workspace volume of the 3R motion has a peak value for each angle ϕ while the minimum limb length l_min corresponding to the peak value increases when ϕ increases from 50° to 80°. The peak value is bigger when the angle ϕ is larger indicating that a larger rR joint base location angle ϕ can help increase the workspace of the 3R motion when a corresponding limb length l_min is provided. An example of the peak workspace volume V of the 3R motion is shown
in Fig. 8(b) which shows the boundary is symmetrical due to the symmetrical limb arrangement. The maximum rotation about $z$ axis is around ±68° ($c_3 = ±0.675$), around ±58° ($c_1 = c_2 = ±0.56$) about $x$ axis and $y$ axis.

Fig. 8(c) shows the workspace volume of the 3rRPS MPM with 1T2R motion with respect to the same limb length range ($l_{\text{min}}$ from 1.3 to 4) and variable rR joint base location angle $\phi$. There is a clear trend that the workspace volume increases when the minimum limb length $l_{\text{min}}$ increases. A bigger angle $\phi$ provides larger $V$ when $\phi$ is less than 70° and $l_{\text{min}}$ is over 2.5 while the workspace volume decreases when $\phi$ is 80° (purple line). Thus to have a good workspace volume, a longer $l_{\text{min}}$ and an angle $\phi$ close to 70° will be good design values. An example of the workspace volume $V$ of the 1T2R motion is shown in Fig. 8(d) which shows the boundary is also symmetrical. The maximum translation along $z$ axis is around 2.1 (2.72 $\leq p_z \leq$ 4.82), with rotation angle $-60.6°$ to $52.7°$ ($-0.585 \leq c_1 \leq 0.496$) about $x$ axis and ±58° ($c_2 = ±0.53$) about $y$ axis.

Thus, considering the two topologies and the workspace volume curves in Fig. 8, a longer $l_{\text{min}}$ and a larger angle $\phi$ close to 70° are good design values.

(2) Effect of the base radius $r_b$.

By using $r_a = 1$, $l_{\text{max}} = 1.8l_{\text{min}}$, $l_{\text{min}} = 3.1$, the maximum singularity-free workspace volumes with respect to different base radius $r_b$ (from 0.7 to 4.5) and different rR joint base location angle $\phi$ are shown in Fig. 9 for the 3R and 1T2R motion. The general trend is similar for both cases that the peak value of the workspace volume is around the same value for different $\phi$ and it requires smaller base size $r_b$ when angle $\phi$ is bigger to reach the peak volume $V$. It can also be seen that a similar base size $r_b$ can make both topologies reach the maximum singularity-free workspace volume for a given angle $\phi$. For example, $r_b \approx 2.9$ gives the maximum $V \approx 0.85$ for the 3R motion with $\phi = 60°$ (blue curve) in Fig. 9(a) while $r_b \approx 3$ gives the maximum $V \approx 1.6$ for the 1T2R motion with same $\phi = 60°$ (blue curve) in Fig. 9(b). This makes it easy to select base size $r_b$ by giving rR joint base location angle $\phi$ or inversely.

(3) Effect of the platform radius $r_a$.

By selecting $r_b = 2$, $l_{\text{max}} = 1.8l_{\text{min}}$, $l_{\text{min}} = 3.1$, the maximum singularity-free workspace volume with respect to different base radius $r_a$ (from 0.3 to 4.1) and different rR joint base location angle $\phi$ are shown in Fig. 10 for the 3R and 1T2R motion. Generally, a smaller platform size $r_a$ will provide larger workspace volume $V$ for both cases. The increase of angle $\phi$ will increase the volume $V$ a lot in 3R motion when $\phi$ is less than 70° as in Fig. 10(a) and it drops a lot for $\phi = 80°$ while $V$ is almost zero when $\phi = 50°$. Thus the trend is similar for the 1T2R motion in Fig. 10(b) but angle $\phi$ does not affect the workspace volume $V$ as much as that in the 3R case. Thus, a smaller platform size $r_a$ and a larger angle $\phi$ close to 70° are preferable.
The above gives a general idea of the effect of those key parameters on the maximum singularity-free workspace of both 3R and 1T2R motion of the 3rR PS MPM. This provides references at the initial stage of the mechanism design. In the following, a systematic way will be shown on the optimal design considering both workspace and kinematics performance.

7. Optimal design of the 3rR PS MPM

As mentioned in Section 6, each topology of the 3rR PS MPM is a parallel mechanism and there is an optimal design for it based on selected design criteria. To have an optimal design of the metamorphic parallel mechanism to cover all working topologies with different motion types is very challenging and time consuming. In this section, the two main topologies of 1T2R motion ($\theta_1 = \theta_2 = \theta_3 = 0$) and 3R motion ($\theta_1 = \theta_2 = \theta_3 = \pi/2$) will be considered together in the optimal design which gives the best combined performance for both topologies.

7.1. Design variables and performance indices

As discussed in Section 6, key parameters of the 3rR PS MPM in the optimization are the base and platform sizes ($r_b$ and $r_a$), rR joint base location angle $\phi$ and the limb length range ($l_{\text{min}} \leq l \leq l_{\text{max}}$). Considering practical mechanical limb strokes, it is commonly $l_{\text{max}} = 1.8l_{\text{min}}$, which means the stroke of the limb can be eighty percent of its minimum length. Then $l_{\text{min}}$ will be taken as one of the key parameters in the design. To have a relative relation, the length parameters are normalized by the base size $r_b$ as $\lambda_a = r_a/r_b, \lambda_{l_{\text{min}}}$ shows the ratio of the minimum limb length over the base size.

In addition to the maximum singularity-free workspace, kinematics performance of the parallel mechanism will be another objective in the optimal design. For the kinematics performance, condition number $k_i = \sigma_{\max}/\sigma_{\min}$ ($\sigma_{\max}$ and $\sigma_{\min}$ are the maximum and minimum singular values of the Jacobian matrix) is a widely used parameter in parallel mechanism design and optimization [50]. For the 3R topology, the Jacobian matrix has unified unit of rotation angles as in Eq. (A5) in the Appendix A. However, the 1T2R topology has coupled translation and rotation due to which the Jacobian matrix has mixed units which causes inconsistent condition numbers in representing kinematics performance. In this paper, the condition number is calculated using the dimensional homogeneous Jacobian matrix [51] which is derived in the Appendix A.
Optimal design of the 3RPS MPM in this paper is to find the best parameter set to have maximum singularity-free workspace with good kinematics performance covering the two topologies of 1T2R motion ($\theta_1 = \theta_2 = \theta_3 = 0$) and 3R motion ($\theta_1 = \theta_2 = \theta_3 = \pi/2$). Thus, the optimal design cost function can be given as:

\[
\begin{align*}
\text{maximize} & \quad V \\
\text{maximize} & \quad k = \frac{V}{\int_V k \, dV} \\
\end{align*}
\]  

Subject to: 

- $-\pi/3 \leq \psi_i \leq \pi/3$,
- $0.3 \leq \lambda_a \leq 1$,
- $0.5 \leq \lambda_{l_{\text{min}}} \leq 1.6$,
- $40^\circ \leq \phi \leq 80^\circ$,
- limb distance $\leq 0.01$,

where $V$ is the maximum singularity-free workspace volume, $k$ is the inverse average condition number in the workspace $V$ and is between 0 and 1. The best kinematics performance corresponds to the value 1 when the velocity mapping is isotropic.

7.2. Optimal design

Based on the optimal design function in Eq. (23), the combined effect of the key parameters on the maximum singularity-free workspace and kinematics performance has been calculated and the results are illustrated in Fig. 11 for both 3R and 1T2R topologies. In general, a larger singularity-free workspace corresponds to a worse average kinematics performance. A smaller platform size ($\lambda_a$) gives a larger singularity-free workspace for both topologies as shown in Fig. 11(a) and (c) in which the blue one ($\lambda_a = 0.3$) shows the best and the red one ($\lambda_a = 1$) is the worst. This is directly opposite to the kinematics performance as in Fig. 11(b) and (d) in which the red ones provide higher numbers while the blue ones are at the bottom.

For the 3R topology, an approximate ratio $\lambda_{l_{\text{min}}}/\phi = 1$ between the minimum leg length and R joint base location angle $\phi$ will give a large workspace for a given platform size as shown by the bump parts of each color in Fig. 11(a). The maximum singularity-free workspace

![Fig. 11. Optimal design of the 3rRPS MPM (blue for $\lambda_a = 0.3$, green for $\lambda_a = 0.5$, yellow for $\lambda_a = 0.8$, red for $\lambda_a = 1$). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)](http://dx.doi.org/10.1016/j.mechmachtheory.2015.08.005)
workspace increases when $\lambda_{\text{min}}$ and $\phi$ increase at the same time. The largest workspace is represented by the point on the blue surface ($\lambda_{\text{a}} = 0.3$) with $\lambda_{\text{min}} = 1.6$, $\phi = 64^\circ$. For each platform size, it can also be found that when the limb length is not enough, the workspace is zero. This happens for a small $\phi$ with a large $\lambda_{\text{min}}$ or a big $\phi$ with a small $\lambda_{\text{min}}$. As mentioned above, the kinematics performance has an opposite trend with workspace as in Fig. 11(b). For a fixed platform size, the average condition number increases when both $\lambda_{\text{min}}$ and $\phi$ decrease at the same time. The best kinematics performance is represented by the peak point on the yellow surface ($\lambda_{\text{a}} = 0.8$) with $\lambda_{\text{min}} = 0.8$, $\phi = 60^\circ$.

For the 1T2R topology, surfaces of both workspace and kinematics performance are smoother than the 3R case as in Fig. 11(c) and (d). The trend is also clear that when the minimum leg length $\lambda_{\text{min}}$ increases, the maximum singularity-free workspace increases while the average condition number decreases. A smaller rR joint base location angle $\phi$ is preferable considering the kinematics performance while a specific value (around $\phi = 70^\circ$) provides the largest singularity-free workspace for a fixed platform size ($\lambda_{\text{a}}$).

To conclude the above optimal design results, a larger angle $\phi$ close to $70^\circ$, a bigger minimum limb length $l_{\text{min}}$, a smaller platform size $r_o$ will provide the best set of parameters to have a maximum singularity-free workspace for both 3R and 1T2R motion of the 3rRPS MPM. However, the kinematics performance represented by the average condition number of the Jacobian matrix has an opposite trend. A smaller $\phi$, smaller minimum limb length $l_{\text{min}}$, and a bigger platform size $r_o$ will provide better average kinematics performance. A trade-off needs to be made between the two performance objectives and also between the two topologies which share the same mechanical parameters. A combined criterion can be given as

$$
\text{maximize} \quad C = w_1(V_{3R} + w_2k_{3R}) + w_2(V_{1T2R} + w_3k_{1T2R})
$$

(24)

where $w_1$ and $w_2$ are the weights of the 3R topology and the 1T2R topology in the objective function with $w_1 + w_2 = 1$, $0 \leq w_1, w_2 \leq 1$, $w_1$ and $w_2$ ($i = 1$ for 3R, $i = 2$ for 1T2R) are the weights for maximum singularity-free workspace and kinematics performance of each topology with $w_1 + w_2 = 1$, $0 \leq w_1$, and $w_2 \leq 1$. $V_{3R}$ and $V_{1T2R}$ are the normalized workspace and $0 \leq V_{3R}, V_{1T2R} \leq 1$. As mentioned above, the inverse averaged condition numbers $k_{3R}$ and $k_{1T2R}$ follow $0 \leq k_{3R}, k_{1T2R} \leq 1$.

An example can be given as $w_1 = 0.4$, $w_2 = 0.6$, $w_1 = 0.5$, $w_1 = 0.5$, $w_2 = 0.7$, $w_2 = 0.3$, which means the performance of the 3R topology weighs forty percent and the 1T2R topology contributes sixty percent to the overall objective. For the 3R topology, workspace and kinematics performance have equal weight while workspace shows more important with seventy percent in the 1T2R topology optimization. Based on those, the best performance is found at $C = 0.637$, with $\lambda_{\text{a}} = 0.3$, $\lambda_{\text{min}} = 1.6$, and $\phi = 64^\circ$, which is on the blue surface in Fig. 11. This shows that the workspace dominates the result. If changing weights of the workspace to be $w_1 = 0.3$, $w_1 = 0.7$, $w_2 = 0.5$, $w_2 = 0.5$, the result will be $C = 0.534$, with $\lambda_{\text{a}} = 0.8$, $\lambda_{\text{min}} = 0.6$, and $\phi = 60^\circ$, which corresponds to a point on the yellow surface in Fig. 11. Thus, priorities represented by the function weights can be given to the topologies and their workspace or kinematics performance in the optimization. Then Eq. (24) will give the optimal result with the best combined performance.

8. Reconfiguration strategy and mechanism design

Reconfiguration of the 3rRPS metamorphic parallel mechanism comes from reconfiguration of its rR joint. Thus the rR joint tuning is a key step in the configuration change between the 3R and 1T2R motion. One solution is proposed as illustrated in Fig. 12 and a worm gear system is used for the rR joint tuning. A prototype of the rR joint is shown in Fig. 12(a) in which the rotation bar is attached with the worm wheel which can be rotated with respect to the base ring by the worm which realizes the alteration of the rR joint axis $u$ and the axis can be fixed by locking the worm control. A small motor can be attached to the worm in each rR joint to tune the rR joint axis in the 3rRPS MPM as in Fig. 12(b). A home position for each limb can be defined as a configuration that the limb axis is

![Fig. 12. Worm gear based independent rR joint tuning.](image-url)
perpendicular to the base ring plane. In this configuration, the base ring rotation axis passes by the spherical joint center in the limb and the rR joint tuning becomes a local limb rotation without any effect to the platform motion. At the same time, there is also no load needs to be conquered by the worm gear system which only needs a small motor for the tuning motion.

Another solution is proposed as in Fig. 13 and the rR joint reconfiguration relies on a bevel gear system. Similar to the worm gear solution, the rotation bar of the rR joint is attached to a bevel gear which can be altered by another bevel gear. In the 3rRPS MPM, a main bevel gear is used as the input with a motor input and it controls the bevel gear of the rR joint in each limb through an intermediate bevel gear as in Fig. 13. In order to save energy in reconfiguring the parallel mechanism, it needs all three limbs to be in their home positions at the same time.

It can be seen that the worm gear solution gives flexibility of controlling each rR joint independently while the bevel gear solution tunes all three limbs in a synchronized way. The former needs three small motors and the latter needs only one motor input. The bevel system will provide symmetrical rR joint axes in the 3rRPS MPM when the initial configuration are symmetrical. This might be preferred as generally symmetrical workspace and kinematics performance are used in applications. The worm gear system can be selected if non-symmetrical configurations are needed.

9. Conclusions

This paper introduced a reconfigurable revolute (rR) joint which qualified the new 3rRPS metamorphic parallel mechanism to be able to provide both 3R and 1T2R motion independently. Since the two motion types shared the same parallel mechanism structure, a unified forward kinematics solution from a 16th order polynomial in one unknown was solved analytically for both cases using the geometric constraints from the limbs. Calay formula representing 3D rotation was introduced to describe the mobility change resulted from the rR joints and its three Rodriguez–Hamilton parameters simplified the analysis with clear physical constraint meaning. More than that, those three parameters also showed advantages in representing singularity loci and singularity-free workspace. A multi-objective function including maximum singularity-free workspace and kinematics performance was used in optimization design of the key parameters. The results showed that a trade-off between the two criteria should be made as opposite trends were shown for the same parameter change. In addition to that, performance weights of the 3R and 1T2R topologies should be also considered as the two shared the same mechanical parameters. This was represented by a unified objective function with variable weights. Two examples were given to demonstrate the optimal design results with different performance priorities. The introduced new parallel mechanism covers the two very useful motion types 3R and 1T2R which have potential applications as machining tools, rehabilitation platforms and robotic surgery instruments. Future work will focus on the optimal design with more performance indices and a prototype implementation.

Appendix A

Since the 1T2R topology has one translation and two rotation motions, the actuation Jacobian involves both linear and angular velocity mappings. Thus, its singular values are not in the same unit and its condition number cannot be used directly for kinematics performance evaluation. Following this, the approach of mapping the platform velocity to linear velocities in some directions at selected points on the platform representing the platform mobility [51] is used. This mapping provides a uniform unit between the linear platform point velocities and linear actuation limb inputs. To present the motion of the platform, linear velocities along \( n = (0,0,1) \) at
the three spherical joint centers $A_1, A_2$ and $A_3$ are selected. Then these linear velocities can be expressed by the platform velocity in the platform coordinate frame as:

$$v_p = [v_1, v_2, v_3]^T = J_p M^T S_G$$

(A1)

where $v_i$ is the linear velocity along $n$ at the selected point, $J_p = [S_{n1} S_{n2} S_{n3}]^T, M = \begin{bmatrix} R & 0 \\ 0 & R \end{bmatrix}, S_{ni} = [n, a_i \times n]^T, (i = 1, 2, 3), a_i$ is the vector of point $A_i$ at which linear velocities are selected.

From Eq. (20), there is

$$J_S = \begin{bmatrix} J_{a1} \\ J_{a2} \\ J_{a3} \end{bmatrix} S_G = \begin{bmatrix} 0 \\ 0 \\ I_1 \\ I_2 \\ I_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ I_a \end{bmatrix}.$$

(A2)

Then

$$S_G = (J^T J)^{-1} J_a I_a.$$

(A3)

Combining Eqs. (A1) and (A3), the selected linear velocities can be obtained directly from the linear actuation input velocities:

$$v_p = J_p M^T (J^T J)^{-1} J_a I_a = J_{a3r} I_a$$

(A4)

where $J_{a3r} = (J_p M^T (J^T J)^{-1} J_a)$ is the $3 \times 3$ dimensional homogeneous Jacobian matrix with unit transformation.

For the 3R topology, the unit of the Jacobian matrix is unified so it can be directly obtained from Eq. (20) as:

$$J_{a3r} = \begin{bmatrix} b_1 \times s_1 & s_1 \\ b_2 \times s_2 & s_2 \\ b_3 \times s_3 & s_3 \end{bmatrix}.$$

(A5)

The condition number of $J_0$ and $J_{a3r}$ are used in the optimal design.
